Background: Post-mortem cardiac magnetic resonance (CMR) is a non-invasive alternative to conventional autopsy. At present, diagnostic guidelines for cardiovascular conditions such as hypertrophic cardiomyopathy have not been established. We correlated post-mortem CMR images to definite conventional autopsy findings and hypothesised that elevated T2-weighted signal intensity and RV to LV area ratios can identify myocardial infarction and pulmonary emboli respectively.

Methods: For this unblinded pilot sub-study, we selected cases from the original blinded study that compared post-mortem imaging to conventional autopsy in patients referred for coronial investigation between October 2014 to November 2016. Three groups of scans were selected based on the cause of death identified by conventional autopsy: non-cardiovascular causes of death with no structural cardiac abnormality i.e., control cases, acute/subacute myocardial infarction and pulmonary emboli. Left ventricular (LV) wall thickness, LV myocardial signal intensity and ventricular cavity areas were measured.

Results: Fifty-six scans were selected [39 (69.6%) males]: 37 (66.1%) controls, eight (14.3%) acute/subacute myocardial infarction and eleven (19.6%) pulmonary emboli. The median age was 61 years [Interquartile range (IQR) 50–73] and the median time from death to imaging and autopsy was 2 days (IQR 2–3) and 3 days (IQR 3–4). The septal and lateral walls were thicker [15 mm [13–17] and 15 mm [14–18]] on post-mortem CMR than published ante-mortem measurements. Areas of acute/subacute myocardial infarction had significantly higher T2-weighted signal intensity (normalised to skeletal muscle) compared to normal myocardium in those who died from other causes [2.5 [2.3–3.0] vs. 1.9 [1.8–2.3]; P<0.001]. In cases with pulmonary emboli, there was definite RV enlargement with a larger indexed RV to LV area ratio compared to those who died from other causes [2.9 [2.5–3.0] vs. 1.8 [1.5–2.0]; P<0.001].

Conclusions: We present potential post-mortem CMR parameters to identify important cardiovascular abnormalities that may be beneficial when conventional autopsy cannot be performed. In patients without cardiovascular disease, LV wall thickness was found to be unreliable in diagnosing hypertrophic cardiomyopathy without histological and/or genetic testing. Elevated T2 signal intensity and RV to LV area ratios may be useful markers for acute/subacute myocardial infarction and pulmonary emboli. Larger studies will be necessary to define cut-offs.

Keywords: Post-mortem cardiac magnetic resonance; conventional autopsy; myocardial infarction; pulmonary emboli; hypertrophic cardiomyopathy
Introduction

Conventional autopsy is considered the ‘gold standard’ for post-mortem examination but due to declines in referrals and an increasing need for a non-invasive alternative, post-mortem cardiac magnetic resonance (CMR) has become a popular option (1,2). Post-mortem CMR has been shown to be helpful in identifying some cardiovascular abnormalities and the cause of death without the need for an invasive examination (3-5). In one study of patients younger than 35 years of age, dedicated post-mortem MR imaging of the heart correctly identified the diagnosis of all patients with cardiovascular abnormalities on conventional autopsy (3). Another study subsequently found that when the radiologist was confident about the cause of death, 40% of the cases referred for coronial investigation would not require a conventional autopsy (6). Despite these previous results, CMR has been found to be less accurate than conventional autopsy for identifying common cardiovascular abnormalities such as hypertrophic cardiomyopathy (HCM), acute/subacute myocardial infarction and pulmonary emboli (7). It remains common practice to use ante-mortem criteria to diagnose pathological conditions despite significant post-mortem changes to the structure and composition of organs. Moving forward, it will be important to develop dedicated post-mortem CMR guidelines to differentiate normal structures from pathological conditions.

In this unblinded pilot study, we correlated post-mortem CMR images to the definite findings of conventional autopsy and aimed to identify diagnostic parameters. We hypothesised that elevated T2-weighted signal intensity and ventricular cavity area measured from pathological conditions.

Methods

The study was conducted in accordance with the Declaration of Helsinki (as revised in 2013). The State Coroner for South Australia approved a joint initiative between Forensic Science South Australia and the South Australian Health and Medical Research Institute (SAHMRI) and performed in accordance with NHMRC human ethics guidelines. Informed consent was taken from all the patients.

Study design and patient population

In this retrospective study, CMR scans were selected from our original blinded study (7), where we evaluated the accuracy of post-mortem CMR in identifying causes of death as reported by autopsy between October 2014 to November 2016. For the current study, the same investigators selected cases reported to have either acute or subacute myocardial infarction, pulmonary emboli or no structural cardiac abnormality (i.e., control cases) on autopsy. The investigators than re-evaluated the CMR scans for myocardial wall thickness, myocardial signal intensity and ventricular cavity area. At the time of autopsy, de-identified details of the death, some limited medical history from the police report and information obtained directly from family members were available. The results of previous investigations such as electrocardiography were not available.

Cardiac magnetic resonance imaging

MR imaging was performed on a Siemens Sonata 1.5T system (Siemens Medical Solutions USA, Inc, Malvern, PA, USA). The deceased individuals were scanned in the supine position within two non-ferrous body bags. The following sequences were acquired: T2 short tau inversion recovery (STIR) sequence was acquired in multiple long axis cardiac planes; left ventricular long axis (LVLA), right ventricular long axis (RVLA), four-chamber, left ventricular outflow tract (LVOT) and right ventricular outflow tract (RVOT). In addition, T2 turbo spine echo (TSE) and T2 STIR sequences were acquired according to the cardiac axis in the short axis (8–12 slices) plane through the entire cardiac mass from base to apex. Image parameters: repetition time =8 ms; echo time =500 ms; flip angle =90 degrees; fractional shortening =1.5 ms; slice thickness 5.0 mm; matrix 168x184; and temporal resolution =40 ms. Images were reviewed by two cardiologists (RP, Level III SCMR and GF-Level III SCMR).
SCMR).

**Cardiac magnetic imaging analysis**

All scans were transferred to a dedicated computer where myocardial wall thickness, myocardial signal intensity and ventricular areas were measured on the Horos workstation version 3.3.6. Left ventricular wall thickness measurements were taken at standard anatomical regions; septum, anterior, lateral and inferior walls from T2 short-axis images in the mid ventricular slice at the level of the papillary muscles. At each position, the average of three separate measurements were reported. Subacute myocardial infarction was diagnosed on conventional autopsy with the corresponding CMR region used to measure signal intensity. Signal intensity measurements for normal myocardium was performed at standard anatomical regions. Three region of interest (ROI) circles measuring 0.5 cm² were manually contoured and standardised to skeletal muscle (right deltoid). The median value of the three measurements were reported. RV and LV areas were measured by manually drawing endocardial borders on four-chamber images and indexed to body surface area; marked coagulation in the right atrium and ventricle made it difficult to recognise the endocardial border in short-axis views. All measurements were performed by both GF and RP.

**Conventional autopsy and definitions**

Conventional autopsy was performed in a single high-volume centre by an experienced pathologist (NL) as described previously (7). Cardiomegaly was assessed with reference to published ranges for post-mortem heart weight (8,9). Left ventricular hypertrophy was diagnosed by the pathologist guided by published guidelines (10,11). Acute and subacute myocardial infarction were defined by the presence of intracoronary thrombus and/or interstitial oedema, coagulative necrosis (pyknosis, karyorrhexis) or poly-mononuclear cell infiltration and macrophages, lymphocytes or scant collagen (12). Pulmonary emboli were defined as laminated and non-adherent clots.

**Reproducibility**

Inter-observer variability was assessed by comparing independent measurements by the primary operator (GF) and a second blinded CMR cardiologist (RP). The co-efficient of variation was determined by dividing the difference between the measurements by the mean measurement for the two operators. Agreement between the measurements and the methods was further analysed using the intra-class co-efficient as described by Shrout and Fleiss (13). The inter-observer reproducibility was assessed using intra-class correlation and Bland-Altman analysis by calculating the bias (mean difference) and the 95% limits of agreement (1.96 SD around the mean difference).

**Statistical analysis**

All values are given as median and interquartile range (IQR). A P value <0.05 was considered significant. Numerical data was performed using Microsoft Excel and Statistical Practice for the Social Sciences (SPSS) software (Version 21, Armonk, NY: IBM Corp). Gaussian-distribution was assessed using the Kolmogorov-Smirnov test with a P value <0.05 considered significant. Differences in continuous variables between the three groups were assessed using an independent t-test and differences in categorical variables were assessed using Fisher’s exact probability test. The inter-observer reproducibility was assessed using intra-class correlation and Bland-Altman analysis by calculating the bias (mean difference) and the 95% limits of agreement (1.96 standard deviation around the mean difference). Receiver operator characteristics (ROC) curve analysis was used to determine the area under the curve and the optimal cut-off values of myocardial signal intensity and RV to LV area ratio. Comparison of the area under the ROC curves was performed using the method described by Hanley et al. (14).

**Results**

**Baseline patient characteristics**

Fifty-six post-mortem CMR scans were selected [39 (69.6%) males] with a median age at death of 61 years [Interquartile range (IQR) 50–73] and a median time from death to imaging and autopsy of 2 (IQR 2–3) and 3 days (IQR 3–4), respectively. From conventional autopsy, twenty-nine (51.8%) had a non-cardiovascular cause of death, eight (14.3%) had no identifiable cause but no structural cardiovascular abnormality, eight (14.3%) died from acute or subacute myocardial infarction and eleven (19.6%) died from pulmonary thrombi. 36 (64.3%) were found dead after an unnoticed collapse and 20 (35.7%) had a witnessed collapse and died after unsuccessful resuscitation. Forty-six (82.1%) died at their place of residence, four (7.1%) died...
while admitted in hospital (two had sepsis, one died from pulmonary emboli following complex surgery and one had no identified cause of death), four (7.1%) collapsed and died while driving a car or bike and two (3.6%) collapsed and died while shopping; Table 1.

### Reproducibility

The distribution of myocardial wall thickness, myocardial signal intensity and ventricular areas were Gaussian in all three groups. We were able to measure these parameters
with a high degree of inter-observer reproducibility and intra-class correlation coefficient equal to 0.86 [95% confidence interval (CI), 0.73–0.93; P<0.001]. For the three parameters, there was a slight bias 0.86±1.68, 1.6±6.8 and 0.09±0.22 but no tendency and only 2/56, 1/56 and 2/56 values were slightly outside the limits of agreement. The intra-class correlation coefficient was strong for (0.92 with 95% CI, 0.81–0.96, 0.92 with 95% CI, 0.82–0.96 and 0.86 with 95% CI, 0.73–0.93).

**Left ventricular wall thickness**

In all three groups, the difference between the CMR and autopsy measured LV septal wall [14 [13–16] vs. 16 [13–18], P=0.16] and lateral wall thickness [15 [13–17] vs. 16 [12–17], P=0.43] was not statistically different but thicker than published ant-mortem values (10). In fact, in those with no structural cardiac abnormality, 37.8% (14/37) would satisfy ante-mortem CMR criteria for HCM (wall thickness ≥15 mm) despite none of them having evidence of myocyte disarray on autopsy examination (15.16). In those with acute or subacute myocardial infarction, the median LV wall thickness of infarcted myocardial wall was 13 mm [12–13]. Additionally, there was no difference in wall thickness between those with or without hypertension; P=0.418 and 0.691.

The median CMR septal and lateral walls were significantly thicker for males compared to females but there was no difference between the CMR and autopsy measured LV wall measurements. The septal wall thickness was 15m m [13–17] for males and 13 mm [12–13] for females (P=0.037) and the lateral wall was 16 mm [14–18] for males and 13 mm [12–15] for females (P=0.018).

**Myocardial tissue signal intensity**

In all three groups, non-infarcted septal walls had higher myocardial signal intensity than non-infarcted lateral walls [141SI [111–171] vs. 123 SI [100–158], P=0.093] and greater signal indexed to skeletal muscle [1.9 [1.8–2.4] vs. 1.7 [1.6–2.1], P=0.085] but the difference was not significant. There was no statistical difference in the indexed signal intensity of the septal and lateral walls between males and females (P=0.081 and 0.097).

In those diagnosed with acute or subacute myocardial infarction on conventional autopsy, the corresponding region on CMR had hyper-intense signal intensity on T2 images (indexed to skeletal muscle) compared to normal myocardium in patients with no structural cardiac abnormality or pulmonary emboli [2.5 [2.3–3.0] vs. 1.9 [1.8–2.5], P<0.01; Figure 1 and Table 2]. None of the other patients had areas of hyper-intensity. Using receiver operator characteristics (ROC) curve analysis, an indexed signal intensity ≥2.3 had an area under the curve (AUC) of 0.83; 95% CI, 0.70 to 0.95 with a sensitivity of 89% and specificity of 68% for identifying subacute myocardial infarction in the post-mortem setting.

**Right and left ventricular area assessment**

In those who died with no structural cardiac abnormality or acute/subacute myocardial infarction, there was no statistical difference in median RV and LV cavity areas (indexed to body surface area); 6.0 [4.9–7.5] vs. 6.3 cm²/m² [5.7–6.5] and 3.6 cm²/m² [2.9–4.1] vs. 3.5 cm²/m² [3.1–3.6], P=0.619 and P=0.606, respectively. In these two groups, the RV to LV area ratio was 1.8 [1.5–2.0] and 1.9 [1.6–2.1], P=0.662. There was no significant difference in RV, LV area or RV to LV area ratio between males and females. P=0.381, 0.812 and 0.102.

In those who died from pulmonary emboli, the RV to LV area ratio were significantly higher than those who died with no structural cardiac abnormality or acute/subacute myocardial infarction [2.9 [2.1–3.0] vs. 1.8 [1.4–2.0], P<0.01; Figure 2 and Table 3]. Using ROC curve analysis, a RV to LV area ratio ≥2.3 had an AUC of 0.931; CI, 0.85–1.00 with a sensitivity 85% and a specificity of 84% for identifying pulmonary emboli.

**Discussion**

Post-mortem CMR is a non-invasive alternative in the investigation of coronial deaths where conventional autopsy cannot be performed (6). In this pilot study, we correlate conventional autopsy findings to CMR imaging and assess post-mortem CMR parameters such as LV wall thickness, myocardial signal intensity and ventricular cavity area. The major findings of this study are: (I) In the post-mortem setting, myocardial wall thickness is not reliable to diagnose hypertrophic cardiomyopathy without histological and/or genetic assessment. (II) Autopsy proven acute or subacute myocardial infarction can be suspected by an indexed (to skeletal muscle) myocardial signal intensity ratio ≥2.3. (III) Autopsy proven pulmonary emboli can be suspected on CMR by an indexed RV to LV area ratio ≥2.3.

During the post-mortem process, bodies are exposed...
to cold temperatures and putrefaction that can change the structure and composition of organs. As a result, it can be difficult to identify pathological abnormalities on post-mortem MR and accurately diagnose some cardiovascular conditions. In a group without cardiovascular disease or histological evidence of hypertrophic cardiomyopathy on autopsy, we found that the septal and lateral walls were thicker than ante-mortem measurements in comparable patients (15). Supporting this finding, a previous study compared ante-mortem and post-mortem cardiac CT scans and found that myocardial wall thickness was increased on post-mortem images even in those without cardiovascular disease (16). At present, there are no post-mortem imaging guidelines for HCM, making the diagnosis difficult without histological confirmation of myocyte disarray and/or identifying known gene mutations. Moving forward, dedicated post-mortem cut-off values will need to be validated to improve the accuracy of the CMR imaging in this setting.

Myocardial infarction is a common cause of unexplained death but an accurate diagnosis with post-mortem CMR is difficult due to the poor resolution of coronary arteries and the inability to deliver contrast. Although criteria for identifying infarcted myocardium on post-mortem CMR without gadolinium has not been established, it can be visualised by T2-weighted MR sequences (17,18). In fact, one study found that autopsy-identified subacute myocardial infarction showed increased signal intensity on T2-weighted STIR and fluid-attenuated inverse recovery (FLAIR) imaging (17). In our cohort, we found that patients with autopsy confirmed acute/subacute myocardial infarction had increased T2-weighted signal intensity (indexed to skeletal muscle) in corresponding CMR areas. Specifically, we found that an indexed signal intensity ratio of ≥2.3 was accurate

*P<0.05.

in identifying acute/subacute myocardial infarction. To date, there is a paucity of data reporting myocardial signal alterations such as occurs with myocarditis on post-mortem CMR, but potential differential diagnoses need to be addressed in specific studies to define their post-mortem imaging appearance.

From studies examining the accuracy of post-mortem CMR, pulmonary thrombus was often missed or incorrectly diagnosed largely due to the presence of post-mortem clot (7). As such, identifying pulmonary emboli in the post-mortem setting remains challenging. In individuals with autopsy confirmed pulmonary emboli, we found definite RV enlargement on CMR with an indexed RV to LV area ratio >2.3. In support of this finding, an ante-mortem study found that an RV to LV area ratio on cardiac CT was accurate at identifying pulmonary emboli and assessing clinical severity (19). Therefore, measuring ventricular area ratios can be a useful marker to indicate RV and/or pulmonary artery pathology in patients with unexplained death who cannot undergo autopsy. It is acknowledged that these changes may be seen in other RV pathological conditions, where the numbers in our cohort were too small to make robust conclusions but do warrant further investigation.

The results of this pilot study are limited by a single centre involvement and a relatively small number of scans. As such, we suggest that further validation of our proposed CMR parameters be performed in larger studies. Cases were selected from our original blinded study that demonstrated the sensitivity and specificity of post-mortem CMR to identify causes of death (7); however, for this study, the investigators were aware of the results of the autopsy and CMR studies. Ultimately, this may be a potential confounding variable. That said, we felt that evaluating CMR parameters directly against the histopathologic “gold standard” i.e., autopsy would maximize accuracy of our results. The individuals referred for coronial investigation were mainly Caucasoid and therefore the parameters may not be generalisable to other ethnic groups. Similar to ante-mortem MR, post-mortem imaging can identify the coronary arterial course but it does not have the resolution to identify obstructive coronary artery disease. As such, myocardial infarction can only be recognised by examining “downstream” effects within the myocardium. At the time of the study, we did not have access to T1 mapping sequences, but we accept evaluating changes with these sequences may provide additional information. Ventricular hypertrophy was reported with reference to published...
guidelines; however, the final diagnosis was decided by the pathologist and therefore may not be standardized. Three patients in the control group had a history of diabetes mellitus, ischemic heart disease and/or hypertension but the cause of death was non-cardiovascular (trauma, sepsis and toxins). Although there was non-specific fibrosis on histological examination, there was no evidence of structural heart disease or acute/subacute myocardial infarction. Never the less, this may be a confounding factor and needs to be considered. Finally, the time interval from death to post-mortem imaging/examination in our study was relatively short. However, there is uncertainty about the validity of our proposed diagnostic parameters with longer time intervals and more advanced body decomposition,

Conclusions

In this pilot study, we present preliminary data that suggests potential post-mortem CMR parameters for identifying important cardiovascular abnormalities. Measuring LV thickness with CMR alone is not reliable in diagnosing HCM but elevated T2 signal intensity can be used as a marker for acute or subacute myocardial infarction and increased RV to LV area ratios can help identify pulmonary emboli. Larger studies are required to confirm dedicated CMR parameters and enhance the reporting accuracy of post-mortem imaging.
